## 1 Kalman Filter

Lets suppose a data generative process is a linear combination of its past values, i.e. the current process process parameters are a linear combination of previous process parameters. In this respect we can calculate the process parameters by minimising the least squared error between the prediction and the true values,  $\boldsymbol{\omega} = (\boldsymbol{Y}^t\boldsymbol{Y})^{-1}\boldsymbol{Y}^t\boldsymbol{f}$ , where  $\boldsymbol{Y}$  is the input data and  $\boldsymbol{f}$  is the target. But this method requires calculating a new  $\boldsymbol{Y}^{-1}$  (a  $O(n^3)$  operation) when we receive any new data. If the process is generating a time series data (getting data one at a time), then online updating the parameters can be incredibly costly.

However, it can be shown that we can calculate new parameters without calculating a new inverse,  $\omega_n = \omega_{n-1} + L \times (f_n - \omega_{n-1}^t y_n)$ . It means that we can calculate new parameters by updating the old parameters with the scaled prediction error on new data using the old parameters. Of course we need to assume some initial values for our parameters. But, we still do not account for any noise in our process.

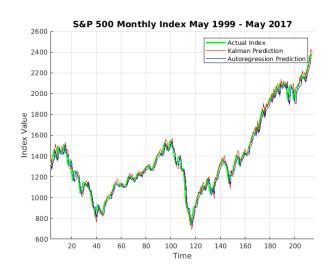

In a Kalman Filter, we may assume a process  $\omega_n = A\omega_{n-1} + \epsilon(n)$ , where the process noise  $\epsilon \sim \mathcal{N}(0, \mathbf{Q})$ . Here we can assume that our parameters are a linear transformation of previous parameters corrupted by Gaussian noise. Similarly, we can assume that our observation  $f_n = \omega_n y_n + \xi(n)$ , where observation noise  $\xi \sim \mathcal{N}(0, R)$ .

[1] claims that we can predict the monthly S&P 500 index using a Kalman filter. In order to verify his claim, I have implemented Algorithm 1 -

```
Algorithm 1 S&P 500 Index Prediction using a Kalman Filter
```

```
1: procedure KALMAN(s, o, \alpha)
                                                                                               \triangleright s = \text{index}, o = \text{order}, \alpha = \text{a constant}
 2:
 3:
          N = size(s, 1);
                                                                                                                          ▶ Number of months
          Y = zeros(N - o + 1, o);
                                                                                                         \triangleright Input data in o order windows
 4:
          \mathbf{W} = zeros(N, o);
                                                                                                                    ▶ Weights at every point
 5:
          e = zeros(N - o + 1, 1);
                                                                                                         ▶ Prediction error at every point
 6:
 7:
         m = ar(s, o);
                                                                                                      ▶ Matlab's autoregression function
 8:
          R = m.NoiseVariance;
                                                                                                               ▷ Observation noise variance
 9:
          \mathbf{w} = (m.a(2:o+1) \times -1)^t;
                                                                                                    ▷ Current weight set to initial value
10:
11:
          A = I_o
                                                                                                                 \triangleright I_o is the o order Identity
12:
          Q = \alpha I_o
                                                                                                                  ▶ Process noise covariance
13:
         P = I_o
14:
                                                                                           ▶ Uncertainity or covariance of parameters
15:
          for n \leftarrow o + 1, N do
16:
              \boldsymbol{y}_n = \boldsymbol{Y}(n,:) = \boldsymbol{s}(n-o:n-1)
                                                                                                           \triangleright Input is last o months' index
17:
18:
              P = APA^t + Q
                                                                                                ▶ Uncertainity on parameters increases
19:
20:
              \boldsymbol{e}(n) = \boldsymbol{s}(n) - \boldsymbol{w}^t \boldsymbol{y}_n
                                                                                                                             ▷ Prediction Error
21:
              \dot{\boldsymbol{K}} = \boldsymbol{P} \dot{\boldsymbol{y}_n} / (R + \dot{\boldsymbol{y}_n^t} \boldsymbol{P} \boldsymbol{y}_n)
                                                                                                                                  ▶ Kalman Gain
22:
23:
              \boldsymbol{w} = \boldsymbol{W}(n,:) = \boldsymbol{w} + \boldsymbol{K}\boldsymbol{e}(n)
                                                                                                                                      ▶ Correction
24:
              P = (I_o - Ky_n^t)P
25:
```

The input at each point in time is past o index values. Observation noise R is taken as the residual variance from an autoregression model using ar function of Matlab's Sys-Process noise cotem Identification Toolbox. variance needed to be tuned via  $\alpha$ . 2a (where I have plotted the cumulative sum of prediction error as a function of  $\alpha$  for a 3rd order filter), indicates that  $10^{-3}$  is a reasonable value for  $\alpha$ . Unless otherwise specified, it can be assumed that a 3rd order filter and autoregression was in use. The parameters were initialised in Line 10 and covariance in Line 14.

I began by generating an artificial time series using white Gaussian noise (Matlab's wgn function) and

Figure 1: Kalman & Autoregression Prediction

(0.5, 0.6, 0.1) weights. The kalman filter quickly stabilises on this data at the expected weights (Figure 2b). After confirming the correctness of the kalman filter, I applied it to real data.

Figure 1 is showing the monthly index values, as well as prediction made from an autoregression and the implemented Kalman filter. Clearly both are very close to the true values of the index. We can also see from Figure 3a that both methods produce very similar error patterns. Figure 3b shows that the errors have very similar spread.

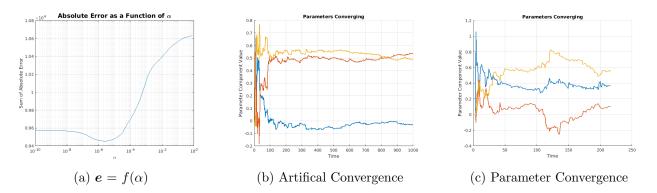

Figure 2: Cumulative Absolute Error as a function of o and  $\alpha$ 

Now we can also observe from Figure 2a that error changes as the choice of  $\alpha$  changes. The  $\alpha$  choice is rather arbitrary and needs tuning. As I mentioned earlier, I chose  $\alpha = 10^{-3}$  for all orders, since it seemed reasonable at most orders.

Figure 2c shows the convergence of the parameters on real data. It demonstrates the recursive correction of weights.

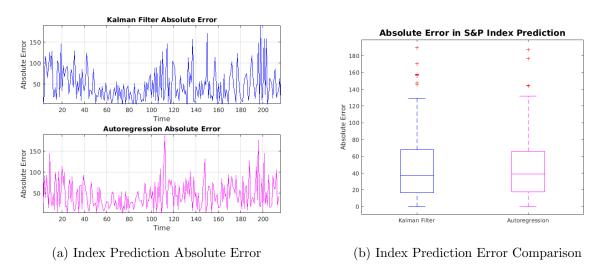

Figure 3: Prediction Error
